Published online: 21 December 2019
chromatography/mass spectrometry and untargeted metabolomics profiling were used to identify metabolites (endogenous and/or drug metabolites) that were significantly different after spironolactone treatment compared with placebo.

**Results:** Spironolactone significantly reduced aortic PWV ($P = 0.047$), but this change was no longer significant after adjustment for the change in daytime systolic BP ($P = 0.132$). Metabolomics profiling identified 43 features (nothing endogenous) that corresponded to downstream spironolactone metabolites, including canrenoate, but none of these correlated with the change in aortic PWV ($P = 0.05$ for all). However, canrenoate was significantly related to the reduction in daytime systolic BP ($r = -0.355$, $P = 0.017$) and 24 hour PP ($r = -0.332$, $P = 0.026$). These associations remained significant on multiple regression analysis after adjustment for sex and body mass index.

**Conclusions:** The downstream spironolactone metabolite canrenoate appears to be an active metabolite with BP-dependent effects on the attenuation of aortic stiffness in people with HRE. This finding, together with the lack of change in endogenous metabolites relating to fibrosis, suggests that the antifibrotic effects of spironolactone could be BP-dependent.

2.1 WALL TENSILE STRESS BUT NOT ATHEROSCLEROTIC RISK FACTORS PREDICTS 3-YEAR CAROTID INTIMA-MEDIA THICKNESS PROGRESSION RATE IN HEALTHY SUBJECTS

Increase in carotid IMT is considered marker of early atherosclerosis. However, experimental and clinical studies suggest that changes in arterial wall thickness may also represent an adaptive response to chronic changes in vessel diameter and/or intraluminal BP aimed to normalize wall tensile stress (WTS).

**Aim of the study:** to assess whether in healthy young-to-middle-aged population a short-term common carotid (CCA) IMT progression rate ($\Delta$IMT) is associated with WTS at baseline.

**Methods:** study population consisted of 749 healthy subjects at average Framingham risk (327 men, age=45±8 years) undergoing carotid US, fasting blood test (LDL-and HDL-cholesterol, triglycerides), oral glucose tolerance test and questionnaire regarding smoking and family history of cardiovascular diseases at baseline and after 3-year follow-up. WTS was calculated as (diastolic BP×CCA radius)/IMT.

**Results:** during a 3-year period, BMI, waist girth, systolic and diastolic BP and plasma glucose increased ($p < 0.001$), HR decreased ($p < 0.001$), and plasma lipids and insulin did not change significantly. CCA diameter ($+0.09±0.30$ mm, $p < 0.0001$) and IMT ($+18.5±5.65$ mm, $p < 0.0001$) increased, whereas WTS ($-0.27±7.67$ kPa, $p < 0.36$) remained unchanged. $\Delta$IMT significantly increased by WTS quartiles at baseline ($p < 0.0001$). In multiple regression model, adjusted for gender, smoking, family history and atherosclerotic risk factors (or their 3-year changes), the only independent determinants of $\Delta$IMT were male gender, age and WTS at baseline ($\beta±SE$: 0.12±0.04, 0.17±0.04 and 0.32±0.04, cumulative $r^2 = 0.20$, $p < 0.0001$).

**Conclusions:** In healthy young-to-middle-aged population, the strongest predictor of short-term IMT progression rate was baseline WTS, followed by age and gender. Thus, IMT increase cannot be always considered marker of atherosclerosis.

2.2 INACCURACIES WITH BRACHIAL AND RADIAL APPLANATION TONOMETRY: SIMILAR IN MAGNITUDE, BUT IN OPPOSITE DIRECTION

T. L. De Backer 1,2, J. S. Vermeersch 1, B. Driehuys 1, Y. Taeymans 1,2, P. Segers 1, L. van Bortel 1,2

In the studied cohort, application tonometry tended to overestimate BA FF (i.e. measuring a flattened curve) by 2.1%, yet it also tended to underestimate RA FF (i.e. measuring a more peaked profile) by 2.5%. Combined, these inaccuracies may amplify the BA/RA ratio.

**Conclusions:** Both RA and BA hand-held application tonometries introduce inaccuracies of similar magnitude but in opposite direction. These inaccuracies may lead to errors in the assessment of central pressure and brachial-to-radial amplification. Whether these inaccuracies may be improved by investigator-independent automated application tonometry should be investigated.

2.3 CLINICALLY APPLICABLE APPROACH TO DISCRIMINATE BLOOD PRESSURE DEPENDENT AND INDEPENDENT CHANGES IN ARTERIAL STIFFNESS

Maastricht University Medical Centre, Maastricht, Netherlands

**Background:** Monitoring of changes in arterial stiffness in hypertensive patients requires consideration of blood pressure (BP) dependent effects. Based on non-invasive measurements of carotid artery BP and cross-sectional area waveforms, we assessed the BP-dependent change in stiffness.

**Methods and Results:** In 13 women and 11 men (mean±SD; SBP/DBP: 157±26/92±10 mmHg, age: 53±15 yrs, BMI: 29±6 kg/m²) tonometric foot-to-foot carotid-femoral pulse wave velocity (cPWVf-f) and common carotid artery cross-sectional area (wall-track) and local pressure waveforms were measured at baseline and at 3-month follow-up. Carotid stiffness was expressed as pulse wave velocity based on the distensibility coefficient (cPWVoc). Per individual, a mono-exponential curve was fitted through baseline carotid diastolic (d), diastolic notch and systolic (s) pressure-area points to enable prediction of the BP-dependent change in stiffness (expressed as cPWVoc*), based on BP values measured at follow-up. In patients whose diastolic blood pressure (DBP) was significantly reduced, cPWVoc* and (measured) cPWVoc were reduced by 1 m/s, similar to the predicted BP-dependent change in stiffness (Table). Patients showing no change in BP showed no change in stiffness. Correlations were: cPWVoc* versus cPWVf-f; r = 0.49 ($p = 0.020$) and cPWVoc* versus cPWVoc; r = 0.45 ($p = 0.037$), while cPWVf-f versus cPWVoc; r = 0.26 ($p = 0.22$).

**Conclusion:** Quantitative assessment of carotid stiffness as function of pressure enables prediction of BP-dependent changes in stiffness. Our clinically applicable approach could help to discriminate pressure dependent and independent effects of antihypertensive treatment on arterial stiffness.
The additive value of measuring subclinical atherosclerosis is 2.5.

However, at this young age there was no impact on vascular structure in intermediate-risk individuals. Our aim was to prospectively evaluate cardiovascular disease (CV) risk-stratification could be improved by non-invasive measurements of atherosclerosis (NIMA) and non-oedematous survivors. After adjusting for age, sex, height and weight, measurements in controls exceeded survivors expressed in mean (SE) standardized units, as follows: PWV 0.35 (0.14, \( p < 0.001 \)), SV 0.44 (0.16, \( p = 0.02 \)), CO 0.53 (0.16, \( p = 0.001 \)), LVOT diameter 0.71 (0.16, \( p = 0.001 \)), SV 0.44 (0.16, \( p = 0.009 \)), and femoral IMT 0.76 (0.19, \( p < 0.001 \)).

Conclusions: Adult survivors of SAM had less arterial stiffness and decreased CO (due mainly to a smaller SV) compared to controls. The nutritional insult in early childhood may have effects on organ growth and therefore cardiac function. However, at this young age there was no impact on vascular structure and function.

The effects of increasing the convective clearance of uremic toxins using high-efficiency on-line hemodiafiltration (ol-HDF) on vascular function and structure in end-stage renal disease patients remain unknown.

Forty-two ESRD patients were randomized to switch from high-flux hemodialysis (HD) to ol-HDF (\( n = 22 \)) or to continue HD (\( n = 20 \)) for 4 months in a prospective double-blind study. Brachial artery endothelium-dependent flow-mediated dilatation (FMD), carotid artery structure and stiffness, and cardiovascular coupling, uremic toxins (beta-2 microglobulin, phosphate) and circulating markers of inflammation (TNF and inducible NO-synthase blood mRNA) and oxidative stress (reactive oxygen species, total antioxidant status) were assessed at baseline and at follow-up.

FMD increased in patients on ol-HDF (152 ± 27 to 177 ± 34 mmHg, \( p < 0.001 \)) but not in patients on HD (165 ± 46 to 161 ± 36 mmHg, \( p = 0.25 \); \( p = 0.01 \) vs. ol-HDF). Peripher al and central blood pressures, augmentation index, carotid artery diameter and intima-media thickness remained stable in both groups Cardiot distensibility was higher (\( p = 0.04 \) vs. HD) and elastic modulus tended to be lower (\( p = 0.09 \) vs. HD) in patients on ol-HDF. Beta-2 microglobulin (\( p = 0.02 \)) and phosphatemia (\( p = 0.01 \)) decreased in patients on ol-HDF. Moreover, in patients on ol-HDF, there was a trend for a decrease in inducible NO-synthase (\( p = 0.07 \)) and plasma nitrite (\( p = 0.06 \)), a marker of NO availability, while TNF increased only in patients on HD (\( p = 0.04 \); \( p = 0.01 \) vs. ol-HDF). Oxidative stress markers remained stable in both groups.

High-efficiency ol-HDF improves endothelial function and decreases arterial stiffness in ESRD patients as compared with high-flux HD. This may be notably related to the reduction in uremic toxins and vascular inflammation.

Severe acute malnutrition (SAM) has oedematous or non-oedematous phenotypes and their metabolic effects may persist into adulthood. We hypothesised that cardiovascular structure and function would differ between phenotypes as young adults and between survivors and persons never exposed to SAM.

**Methods:** We recruited 54 non-oedematous and 62 oedematous adult survivors of SAM, and 45 age/sex/BMI-matched community controls. Standardised measures of anthropometry, blood pressure (BP), 2D-echocardiography, carotid and femoral ultrasound, brachial, radial and carotid tonometry were performed. Cardiac output (CO), stroke volume (SV), left ventricular mass (LVM) index and outflow tract (LVOT) diameter, carotid and femoral intima-media thickness (IMT), carotid-femoral pulse wave velocity (PWV) and augmentation index were derived. Visceral fat mass was assessed by CT scan.

**Results:** Mean (SD) age was 28.8 (7.8) years; 55% were male. Visceral fat mass and BP did not differ significantly between groups. There were no significant differences in cardiovascular measures between oedematous and non-oedematous survivors. After adjusting for age, sex, height and weight, measurements in controls exceeded survivors’ expressed in mean (SE) standardized units, as follows: PWV 0.35 (0.14, \( p = 0.02 \)), CO 0.53 (0.16, \( p = 0.001 \)), LVOT diameter 0.71 (0.16, \( p = 0.001 \)), SV 0.44 (0.16, \( p = 0.009 \)), and femoral IMT 0.76 (0.19, \( p < 0.001 \)).

**Conclusions:** Adult survivors of SAM had less arterial stiffness and decreased CO (due mainly to a smaller SV) compared to controls. The nutritional insult in early childhood may have effects on organ growth and therefore cardiac function. However, at this young age there was no impact on vascular structure and function.
