**Abstract.** The salivary gland proteins of the *Anopheles* (An.) female mosquito play vital roles in the transmission of *Plasmodium* into the human host. A comprehensive understanding of *Anopheles* identity and its related salivary proteins is a key for vector-based malaria control. This research aims to analyse the protein profile and immunogenicity of *Anopheles* salivary gland proteins from 2 potential *Anopheles* vectors, *An. vagus* and *An. sundaicus*. Female *Anopheles* are collected from Bangsring village, Banyuwangi Regency by direct-landing collection. Each species are identified by morphological features and internal transcribed spacer 2 (ITS2). Immunogenic proteins were determined by Western Blotting with IgG from people living in the endemic area as primary antibodies. Immunoblotting results showed the presence of 3 immunogenic protein bands with a molecular weight of 34, 46, and 66 kDa in both species. Furthermore, the 99 kDa protein band was present merely in *An. sundaicus*. Moreover, the result showed that two distinct species have different profiles and immunogenic proteins.

**Keywords:** Immunogenic proteins · salivary gland · vector · *Anopheles* · Malaria

## 1 Introduction

Malaria is a vector-borne disease caused by *Plasmodium* (P.), which is transmitted by female *Anopheles* as a vector. *Plasmodiums* that cause illness in humans are *P. vivax*, *P. falciparum*, *P. ovale*, and *P. Malariae* [1]. *Plasmodium* is transmitted to the human host while the female *Anopheles* bites the human. Mosquito requires blood protein for nutrition and egg development [2]. The transmission of *Plasmodium* is due to the role of salivary gland proteins that mediate the blood meal process of mosquitoes into the human host.

Mosquito saliva contains immunomodulatory and antihemostasis factors [3]-[5]. Immunogenic proteins can modulate the immune system, and against various agents that have a significant role in non-specific and specific immune responses [2]. Immunomodulatory proteins found in Hematophagous Arthropods are the D7 family, SGS (salivary

gland surface), and saglin [6, 7]. D7 family plays its role as a vasodilator, antithrombotic, and immunomodulator [8] in the Culicidae family [2].

Antithrombotic proteins facilitate blood-feeding by preventing the haemostasis process. Based on the function, there are three groups of antithrombotic (1) vasodilator (2) anti-platelet aggregation, and (3) anticoagulant [2]. Vasodilator protein potentially inhibits vasoconstriction and enlarges the artery [2]. Several proteins are known as vasodilatory factors, such as sialokins, adenosine, and maxadilan [2]. Anti-platelet aggregation inhibits some aggregation factors like ADP and thrombin. One of the anti-platelet aggregations is apyrase which plays a role as anti-platelet by catabolizing ADP released and inhibit platelet activation [2]. Apyrase was found in *Aedes aegypti* [9], *Anopheles* [2], and Hemiptera [10]. This indicates that various types and activities of salivary protein are related to the vector species (genus or species-specific).

Some research demonstrates that the saliva of different species or genus has distinct secreted protein and immunogenicity activities [11, 12]. Taxonomical level influences the similarity of salivary protein of *An. albimanus*, *An. arabiensis*, *An. stephensi* and *An. gambiae*. The number of homologous proteins among the *Anopheles* species was the highest among the closely related anopheline species (among *An. gambiae* and *An. arabiensis*) and decreased with increasing phylogenetic distance (among species from the Subgenus *Cellia* [11]).

*Anopheles* is an Arthropod with a high level of diversity. Morphological appearance is insufficient to distinguish the species, especially those closely related or cryptic species [13]. A molecular-based analysis is an approach to understanding the diversity of high organisms using one or more molecular markers. ITS2 (internal transcribed spacer 2) is a widely used molecular marker to determine *Anopheles* species [14]–[16]. It has a vast conservation area, is easy to amplify with PCR, has high variability, and is available in many online databases [14, 17]. A comprehensive understanding of salivary gland protein profile and immunogenicity related to vector identity is a crucial step to intervene in the transmission of disease from vectors to human hosts. It could be the development of biomarkers and vector-based vaccines. The hypothesis of the study is genetically different species of *Anopheles* have different immunogenic proteins. Therefore, this study aimed to determine the profile and immunogenicity of *Anopheles* mosquito proteins related to their genetic diversity analysis using ITS2 molecular markers.

## 2 Materials and Methods

### 2.1 Morphological and Molecular Identification

The specimen of mosquitoes is collected from their natural habitat in Bangsring village, near the coastal area of Bali Bay, and in rural areas of Bangsring village, Banyuwangi. The sampling location is located between latitudes 8°04' S and longitudes 114°25' E. The adult females were collected by direct landing collection using a hand-held aspirator and torchlight from the cowshed from 6 p.m.– 5 a.m. The *Anopheles* were identified based on the book of determination key of insects [18].

Total DNA was extracted using the salting-out method proposed by Aljanabi and Ichiar (1997) and was used as a DNA template for amplification. The ITS2 sequence was amplified using the primers ITS2-F (5'TGT GAA CTG CAG GAC ACA TG 3') and

ITS2-R (5' ATG CTT AAA TTT AGG GGG TA 3') and following reaction mix (50 µl): 1.25 µl primer-F, 1.25 µl primer-R, 21.5 µl sterile ddH<sub>2</sub>O, 25 µl 2x PCR master mix and 1 µl DNA template. The following thermocycler parameters: 94°C for 5 min, 4 cycles at 94°C for 40 s, 94°C for 1 min and 72°C for 1.5 min, 29 cycles at 94°C for 40 s, 51°C for 1 min and 72°C for 5 min then stand by at 16°C. The PCR product will be showed a single band around 500 bp. Then PCR result was sequenced at the sequencing facility of 1st Base Singapore.

## 2.2 Ethical Consideration and Blood Sera Collection

Human blood sera collections were approved by KEPK (The Ethical Committee of Medical Research Faculty of Dentistry Universitas Jember) No. 1034/UN25.8/KEPK/DL/2020, approved on October 19<sup>th</sup> 2020. Sera samples were collected from healthy adult residents living in Bangsring village, Banyuwangi who were exposed by Anopheles. The blood sample was taken from the bronchial vein in the upper arm. 3 mL blood was taken and placed in a vacutainer without heparin. Then, it was kept for 15 to 45 min. The upper transparent layer was taken and centrifuged at 27°C, 3200 rpm for 10 min. The supernatant was then kept at -20°C. Infant Sera was used as a negative control.

## 2.3 Salivary Gland Protein Extraction and SDS-PAGE Analysis

The salivary gland (SG) was isolated by microdissection under a stereomicroscope and was pooled into microtube containing 10 µl PMSF on PBS for 10 pairs of SG. The SG was used as a sample for protein analysis and stored at -20°C. The dissected SG was mixed in 1:1 lysis buffer (Tris-HCL 1 M pH 6.8, glycerol, 0.1% Bromophenol blue, 10% SDS, and sterile H<sub>2</sub>O). The mixture was boiled for 4 min. Then, 20 µL sample was loaded and separated onto 12% separating gel (30% acrylamide/bis-acrylamide, 1.5 M Tris-HCL pH 8.8, 10% SDS, sterile H<sub>2</sub>O, 10% APS and TEMED) and 4% separating gel (acrylamide/bis-acrylamide, 1.5 M Tris-HCL pH 6.8, 10% SDS, sterile H<sub>2</sub>O, 10% APS and TEMED). Molecular weight (MW) pre-stained protein marker (Blue Eye) was loaded onto the gel. The SDS-PAGE was run for 70 min, 150 V, in 1x electrode buffer pH 8.3. The gel was stained for 2 h with Coomassie Brilliant Blue and de-stained for 30 min three times.

## 2.4 Western Blotting

The SDS-PAGE gel was transferred to polyvinylidene difluoride (PVDF) membrane using semidry blotting (Biorad) at 110 mA for 1 h. The membrane was washed with Tris Buffer Saline (TBS) three times, then it was soaked with 5% skimmed milk on TBS for 1 h. Subsequently, the membrane was washed again with TBS three times and incubated with human sera at dilution 1: 250 (v/v) in skimmed milk on TBS overnight at 4°C. Blots were washed with TBS three times then were incubated with goat anti-human IgG labeled alkaline phosphatase at dilution 1:5000 (v/v) for 2 h at room temperature. The PVDF membrane was washed again with TBS three times. Color development was done with NBT-BCIP Phosphatase substrate for 1 min.

### 3 Results and Discussion

In total, 584 individual mosquitoes were collected during landing collection. Morphological identification showed *Anopheles* population in Bangsring village was mainly dominated by *An. vagus* and *An. sundaicus* with a percentage of 75.43% and 23.38%, respectively. Both species are *Cellia* subgenus which has three or more pale bands on the palpus. Moreover, *An. vagus* has 3–5 times apical pale band (Ap) than the subapical dark band (Sd) while *An. sundaicus* has 1/3 length of Sd compared with the Ap. The hind leg. *An. vagus* has a non-speckled hind leg, generally white or black hair in femur and tibia, *An. sundaicus* has speckled femur and tibia on its hind leg [18].

The ITS2 sequence was used as an approach for species confirmation. The PCR-ITS2 yielded a different product size from each species, 498 bp for *An. vagus* and 486 bp

for *An. sundaicus* (not included on the journal). Based on the sequence alignment and comparison on BLAST online software, ITS2 sequence of *An. vagus* from Bangsring has 99,67% similarity with *An. vagus* FJ654649.1 (Table 1), an identified species from East Java [19]. *An. vagus* is widely known as the secondary malarian vector in Sukabumi [20] and Banten [5] and has been approved to be a vector of *Plasmodium vivax* [21]. The ITS2 sequence of collected *An. sundaicus* showed 97,35% similarity with AY768541.1, *An. sundaicus* from Indonesia which has been known as the primary vector of malaria in various regions of Indonesia [22, 23].

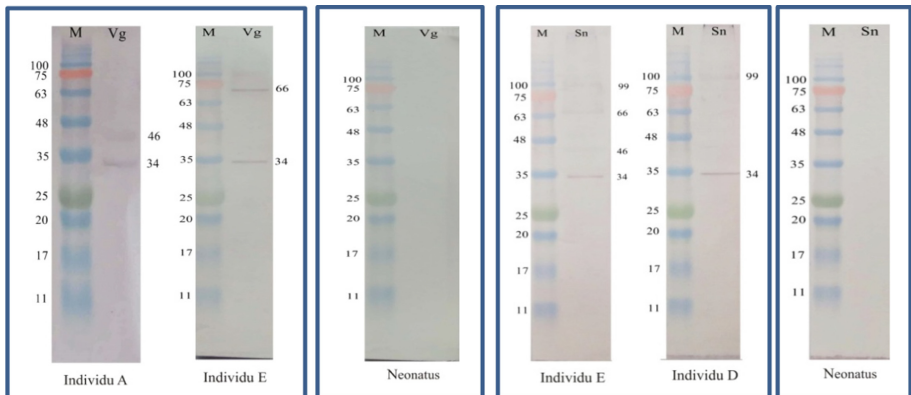

The taxonomic level has an impact on protein similarity. The closer of phylogenetic relationships having likeness in protein profiles and antigenic activities [11]. Some proteins could be a ubiquitous salivary protein that can be found in the salivary gland of other blood-sucking insects [18], could function as housekeeping and secreted protein for blood feeding [11]. The profile of SG proteins is analysed using SDS-PAGE analysis. The salivary gland protein extract (SGE) of *An. vagus* showed 14 dominant bands of protein with molecular weight of 14, 15, 16, 31, 34, 41, 43, 46, 54, 64, 66, 75, 99 and 230 kDa. Whereas, *An. sundaicus* showed 15 dominant protein bands with a molecular weight of 14, 15, 16, 31, 34, 41, 46, 48, 54, 64, 66, 75, 99, 230, and 262 (Fig. 1). Most of the protein are appeared in both *An. vagus* and *An. sundaicus*. These results are supported the previous research mentioned that different species have different protein profiles. The difference of the two species is minor as *An. vagus* and *An. sundaicus* are members of subgenus *Cellia*, causing them to have high salivary protein similarity. Earlier research shows that *An. gambiae* and *An. arabiensis* (*An. gambiae sensu lato*) which were identified using COII molecular marker have 73% of salivary gland protein similarity [11].

The results of western blotting showed that specific proteins of 34, 46 and 66 kDa appeared on both species (Fig. 2). Previous studies revealed these proteins are ubiquitous proteins found in Culicidae and hematophagous Arthropoda [1]. The putative protein of 34 kDa was related to the D7 protein family. D7 protein has been reported to act as an immunomodulator, vasodilator, and anticoagulant in *Ae. aegypti* [22, 23] and *Anopheles* species [1]. Whereas protein of 46 kDa is commonly known as coagulant and anti-inflammation protein, serpin. The putative protein of 66 kDa has been reported as apyrase, a protein that acts as an anticoagulant and platelet aggregation in *Aedes aegypti* [22] and *Glossina* sp. [24].

One specific protein with a molecular weight of 99 kDa, which was only detected in *An. sundaicus* showed immunogenic activity. Furthermore, the negative result appeared in the reaction between individual neonates serum with SGE of *An. vagus* and *An. sundaicus*. The 99 kDa protein, which only appeared on SG of *An. sundaicus* is very likely to be a member of saglin. Nevertheless, this protein is not a species-specific protein. Saglin has been found in *An. gambiae* and *An. stephensi* [7, 25]. Saglin plays a role in the invasion of Plasmodium sporozoite in SG of *Anopheles* [7]. The difference in the profile and immunogenic protein between *An. vagus* and *An. sundaicus* is probably related to the vectorial capacity of *Anopheles* species. Saglin is commonly known as a receptor for malaria sporozoites related to the status of *An. sundaicus* as the primary vector of malaria in various regions in Indonesia [8].

**Fig. 1.** Protein profile of salivary gland extract (sge) *An. vagus* (Vg) and *An. sundaicus* (Sn). Sample from landing collections, isolation of 10 pairs of salivary glands. M (marker).

**Fig. 2.** Different patterns of immunogenic proteins of SGE *An. vagus* (Vg) and *An. sundaicus* (Sn) were identified by Western Blotting method, which were the result of cross reaction with individual human sera (Individu A-E). Three immunogenic proteins of *An. vagus* with molecular weight of 34, 44 and 66 kDa, whereas four immunogenic proteins were identified from *An. sundaicus* i.e 34, 46, 66 and 99 kDa. (M) marker, neonatus (Negative control).

These results could provide a novel target protein for future investigations aimed at malaria transmission, represent the first step toward the identification of immunogenic protein as molecular marker of exposure and vector-based vaccine development. Further analysis targeting the immunogenic proteins highly recommended such as protein identification by LC/MS analysis. But the methodology represented here appears very convenient for initial screening of immunogenic proteins. It provides qualitative data on the detection of immunogenic components of *Anopheles*.

This study highlights the differences in the protein and immunogenicity profile of two different species of *Anopheles*, *An. vagus* and *An. sundaicus* from Bangsring Banyuwangi. The protein profile of salivary gland protein extract (SGE) of *An. vagus* showed 14 dominant bands of protein, whereas *An. sundaicus* showed 15 dominant bands of protein. Three immunogenic proteins of 34, 46, and 66 kDa were identified from both species, whereas protein with a molecular weight of 99 kDa, which only appeared in SGE of *An. sundaicus* were able to cross-react with sera samples from the endemic area. Moreover, the result showed that two distinct species have different profiles and immunogenic proteins.

These present studies showed that two species were successfully identified morphologically and molecularly using ITS2 marker as *An. vagus* and *An. sundaicus*. Though these two species are in the same subgenus, the SDS-PAGE and immunoblotting results showed that distinct species are having different profile and immunogenic protein. These results indicate protein activity of *Anopheles* are likely related to the species identity.

**Acknowledgments.** This study was supported by “Master Grants” and KeRis (Kelompok Riset) of Vector Biology, University of Jember. We thank particularly Mujiono, researcher staff of The Centre for Research and Development of Disease Vectors and Reservoirs, (B2P2VRP) Salatiga, Indonesia for his input during this work.

**Authors’ Contributions.** KS, IW and RO designed the experiments. IW and LNUH analysed the morphological and molecular identification of the *Anopheles*. IW and SW optimized the SDS-PAGE and Immunoblotting protocols. KS and IW analysed data, wrote and edited the manuscript with contributions from all authors. All authors read and approved the final manuscript.
