Abstract

Artificial intelligence decision support system is always a popular topic in providing the human user with an optimized decision recommendation when operating under uncertainty in complex environments. The particular focus of our discussion is to compare different methods of artificial intelligence decision support systems in the investment domain – the goal of investment decision-making is to select an optimal portfolio that satisfies the investor's objective, or, in other words, to maximize the investment returns under the constraints given by investors. In this study we applied several artificial intelligence systems like Influence Diagram (a special type of Bayesian network) and Neural Network to get experimental comparison analysis to facilitate users to intelligently select the best portfolio.

1. Introduction

The investment domain, like many other domains, is a dynamically changing, stochastic and unpredictable environment. Take the stock market as an example; there are more than two thousand stocks available for a portfolio manager or individual investor to select. This posts a problem of filtering all those available stocks to find the ones that are worth investment. There are also vast amounts of information available that will affect the market to some degree.

For all these problems artificial intelligence decision support systems are always the solutions. The decision support systems are to provide the investor with the best decision support under time constraints. For this purpose, we propose several artificial intelligence systems like using the Influence Diagram as the framework and Neural Network to advice users build their own highly successful investment portfolios.

The structure of the paper is as follows. In section 2, we introduced some related works on structures of investment decisions for portfolio managements. In section 3 and 4, we described the frameworks of influence diagram, decision tree and neural networks. In section 5, we specified our experimental settings. In section 6, we showed our experimental results and explanations. And in section 7, we concluded our paper..

2. Related Work

We explored several ways to reduce the complexity of the investment decision deliberation that might cause the investors to lose money under urgent situations, and, at the same time, to provide the highest quality investment recommendations possible.

For portfolio management, Strong [16], Reilly and Norton [13] and Jones [9] brought several traditional portfolio management strategies. And Sycara, et al. [17] focused on using distributed agents to manage investment portfolios. Their system deployed a group of agents with different functionality and coordinated them under case-based situations. They modeled the user, task and situation as different cases, so their system activated the distributed agents for information gathering, filtering and processing based on the given case. Their approach mainly focused on portfolio monitoring issues and has no mechanism to deal with uncertainty. Our systems on the other hand react to the real-time market situation and gathers the relevant information as needed. John, et al. [8] made extensive research on stock selections by applying induction rules into data mining applications. Other related research on portfolio selection problems has received considerable attention in both financial and statistics literature; see Cover [3]and Cover, et al, [4].

In the field of model refinement, there are several approaches. The value of modeling was first addressed by Watson and Brown [22] and Nickerson and Boyd [11]. Chang and Fung [2] considered the problem of dynamically refining and coarsening of the state variables in Bayesian networks. However, the value and cost of performing the operations were not addressed. Control of reasoning and rational decision making under resource constraints, using analyses of the expected value of computation and consideration of decisions on the use of alternative strategies and allocations of effort, has been explored by Horvitz [6] and Russell and Wefald [14] Poh and Horvitz [12] explored the concept of expected value of refinement and applied it to structural, conceptual and quantitative refinements. Their work concentrated on providing a computational method for the criteria to perform the refinement. However, their work did not address the need of a guided algorithm to perform the node refinement throughout the network. In our previous work Tseng, et al, [20], we used guided methods to perform the conceptual refinement for our models. We see significant performance improvement of the models after applying the refinement algorithm. And Tseng [19,20] made extensive researches on applying influence diagram into portfolio selections and comparing our intelligence decision support

system with other artificial intelligence systems, such as C5.0, and made conclusions that our system will handle better than C5.0 in the dynamic environment. Starzyk, et al, [15] also brought Self-Organizing Learning Array system into economical and financial applications by comparing our influence diagrams decision support system.

Besides there is few work on the comparison of different intelligence decision support systems. In our paper you will see how different systems work differently.

3. Influence Diagram

An influence diagram is a special type of Bayesian network (Figure 1), one that contains the decision node and the utility node to provide a decision recommendation from the model. Influence diagrams are directed acyclic graphs with three types of nodes—chance nodes, decision nodes and utility nodes. Chance nodes, usually shown as ovals, represent random variables in the environment. Decision nodes, usually shown as squares, represent the choices available to the decision-maker. Utility nodes, usually of diamond or flattened hexagon shape, represent the usefulness of the consequences of the decisions measured on a numerical utility scale. The arcs in the graph have different meanings based on their destinations. Dependency arcs are the arcs that point to utility or chance nodes representing probability or functional dependence. Informational arcs are the arcs that point to the decision nodes implying that the pointing nodes will be known to the decision-maker before the decision is made.
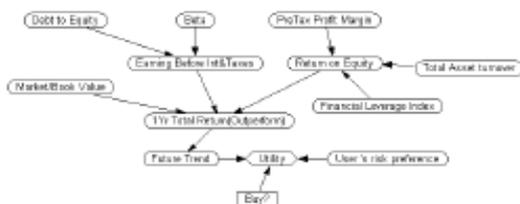

Figure 1. A simple influence diagram

When using an influence diagram for decision support problems, there are some fundamental characteristics of the influence diagram that one must take into consideration. These characteristics influence the data requirements and the choice of the appropriate influence method. The first characteristic is the granularity of the values for each node. This characteristic affects the memory requirement for storing the probabilities and the computational time required for updating the probabilities. The more values within each node, the larger the memory required and the longer it will take to propagate the probability update. The second characteristic is the integration of the user's preference into the utility node. This characteristic will affect the decision outcome of the model. Given different preferences among users, the model might return a different decision recommendation. Another issue of this

characteristic is how to model the user's preference into a set of values for the utility node. Different fields of research have suggested different approaches for this problem. Some suggest learning from the user's behavior, while some suggest obtaining data from a user survey and some simply query the expert and assign subjective values.

The third characteristic to consider is the availability of the knowledge about the structure, probabilistic knowledge for the prior and the conditional probabilities. There are many variables in a specific problem domain and there might exist several concepts in the problem domain that are observationally equivalent, which means they are not distinguishable even with infinite data. To find out which of those are relevant to the problem and the casual relationships among them present a challenge to the knowledge engineer. There has been much research and many tools devoted to the learning of the model structure from the data. [4] For the probability distribution for the node, there are two methods to obtain the probabilities. First, the probability distributions can be based on frequency by obtaining the data from gathered statistics. The second method is to obtain the probability distributions through knowledge acquisition sessions from the domain experts, who convey their subjective beliefs. In both cases, the probabilities can be refined through a feedback mechanism. Finally, the size, topology and connectivity of the model should also be considered. Applying good knowledge engineering techniques [7] throughout the construction of the model will help keep the network manageable.

4. Neural Network

A neural network is a powerful data modeling tool that is able to capture and represent complex input/output relationships. The motivation for the development of neural network technology stemmed from the desire to develop an artificial system that could perform "intelligent" tasks similar to those performed by the human brain. Neural networks resemble the human brain in the following two ways:

1. A neural network acquires knowledge through learning.
2. A neural network's knowledge is stored within inter-neuron connection strengths known as synaptic weights.

The true power and advantage of neural networks lies in their ability to represent both linear and non-linear relationships and in their ability to learn these relationships directly from the data being modeled.

The most common neural network model is the multilayer perceptron (MLP). This type of neural network is known as a supervised network because it requires a desired output in order to learn. The goal of this type of network is to create a model that correctly maps the input to the output using historical data so that the model can then be used to produce the output

when the desired output is unknown. A graphical representation of an MLP is shown below in Figure 2.

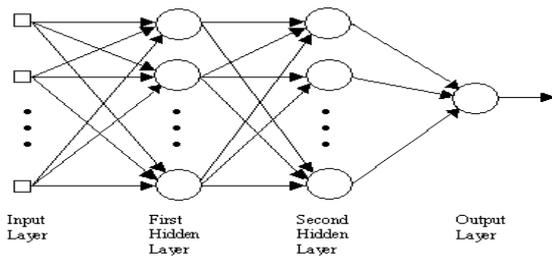

Figure 2. A MLP neural network model

In neural networks, an activation function is the function that describes the output behaviour of a neuron. The most common activation functions are sigmoid and Gaussian functions.

- Sigmoid function $f(\mu_i) = \dfrac{1}{1 + e^{-\mu_i/\sigma}}$

- Gaussian function $f(\mu_i) = ce^{-\mu_i^2/\sigma^2}$

5. Experiment Settings

5.1. Influence Diagram Model

Our influence diagram model of the investment domain consists of a number of stocks for the investors to construct an investment portfolio. The goal is to maximize the profit from the investment portfolio. The experiments are written in C++ and built on top of the Netica Belief network package, running on a LINUX platform.

In the experiments we ran, we selected eight financial ratio data from the S&P 500 companies as the input factors to the system. The training data is collected from the Compustat database from the period of 1993 to 2002. To test the performance, we used the date from the year 2003 and let the system made the decision recommendation on which of the S&P 500 companies to be included in the investment portfolio.

5.2. Neural Network Model

Before a neural network can be trained with these data, they must be normalised, or called in pre-processing phase. The following rule has been used for normalisation derived from Angstenberger (1996):

1. Multiplication of the data by the factor: $\dfrac{0.8}{\max - \min}$;

2. Addition of the offset $0.1 - (\text{factor} * \min)$;

In this way the data can be scaled to the range from 0.1 to 0.9. The trained data can also be transformed back to the original scale, due to the linearity of the formula.

The experiments of neural network model are built on top of the Brainmaker Professional network package, running on a WINDOWS platform. There are total 4483 training data sets, which are eight financial ratio data from the S&P 500 companies

collected from the Compustat database from the period of 1993 to 2002. There are total 500 testing data sets, which are the same categories as the training data except they are from the period of 2003. We conducted extensive experiments and found that the one with the best result was using the following parameters:

- Number of hidden layers: 1
- Input layer 1: Gaussian, 338 neurons
- Output layer: Sigmoid
- Learning rate: Exponential, 1.0

6. Results

The experiment results are summarized in table 1 shown the 2003 performance of all three artificial intelligence techniques that are used to select stocks from S&P 500. The following three subsection sdescribes the detail result from each architecture.

6.1. Influence Diagram Model

On the 2003 test data, the influence diagram portfolio obtains its maximum average annual return performance when the portfolio contains 134 companies out of the 500. The 134 companies produced an average one-year total return of 26.32%, while the average return of all the 500 companies was 19.27%.

6.2. Neural Network Model

Unlike our first model, this portfolio obtains its maximum one year total return performance when the portfolio contains 298 companies out of the 500 companies on the 2003 test data. This portfolio only produces an average one year total return of 12.649, which is even lower than the average of the S&P500's return, which is 19.268. The root mean square error is 0.5032, which is too high to get any reliable results.

It is true that the quality of the forecast is highly dependent on the network parameters. But after carefully analyzed our data, I found that there exist some cross-sectional problems. The 500 companies are chosen from different industries fields and each has its own economic cycles. For example, all the local "dot com" companies were in their recession cycles at the beginning of this century, while the Chinese companies were in their booming cycles, like SOHU and SINA. Besides, the "size effect" [13] is also a critical factor affecting results. The sizes of the companies under S&P500 index are quite different, which make their returns different between large-size companies and small-size companies. All these problems can not be easily distinguished in the general neural network structures.

6.3. Self-Organizing Learning Array (SOLAR) system

Starzyk, et al [15] compared our work with their machine learning technique in (SOLAR) system: A new Self-Organizing Learning Array (SOLAR) system. SOLAR is capable of handling a wide variety of classification problems. It has a regular array structure with sparsely interconnected computing elements and local learning rules. Computing elements choose their connections and define their own functionality, while learning how to best extract information from their input data.

SOLAR was constructed without expertise in this field and has not been refined for this specific problem. 9 individual SOLAR networks were used in this case, each of which yielded 17% to 84% independently, which still shows higher volatility and stochasticity. However, its high average yield made itself worth further research on portfolio selections, though, in Adult Income Classification case [15], Bayes algorithms outperformed SOLAR slightly.

Table 1. Result from three architectures.

	Average one year total return
Influence Diagram	25.32%
Feed-forward Neural Network	12.649%
SOLAR	30.1%

7. Conclusion

We conducted some performance analysis with our systems and compared ours with other intelligence system. Our decision support system uses the influence diagram as the decision model; the structural information of the influence diagram plays an important role on the performance of our system. We obtained the structural information from the domain expert and the information represents what the expert's opinion on the causal relationships among the nodes. From the experiment results, we can see that the influence diagram system works better than many other artificial intelligence systems in a more general situation. This is due to the background information given by the domain expert when constructing the network.

Given the above analysis, we could conclude that by using an artificial intelligence system for portfolio selection has performance edge over the human portfolio manager and the market. The systems we selected for this study are only one among numerous artificial intelligence systems available. We would like to conduct further study to better qualify and quantify various artificial intelligence systems for use in the portfolio selection domain.
